ABSTRACT

Objective: The study was carried out to check the antibiotic susceptibility profile of *Staphylococcus aureus*.

Methods: In this study for the isolation of strain, skin swabs from different parts of the body were taken aseptically with the set protocol. The sensitivity patterns of *S. aureus* were explored with different antibiotics for the treatment of *S. aureus* infections. We have studied the susceptibility pattern of various antibiotics including present all line therapies and other antibiotics using disk-diffusion method.

Results: It has been found that bacteria show the highest sensitivity toward third-line antibiotic tetracycline, trimethoprim, and minocycline. The different concentrations of these antibiotics were used to check the minimum inhibitory concentration and found to be effective even at the lower concentration of 0.01 mcg/disc. Furthermore, the minimum inhibitory concentration of each antibiotic has been calculated to find the most effective antibiotic at low concentration. The isolates are found to be highly resistant toward ampicillin, ciprofloxacin, and cefotaxime.

Conclusion: The research concluded that the bacteria *S. aureus* are found to be more sensitive for chloramphenicol, kanamycin, and trimethoprim in first-line antibiotics, second-line antibiotics, and third-line antibiotics, respectively.

Keywords: *Staphylococcus aureus*, Antibiotic, Zone of inhibition, Minimum inhibitory concentration.

INTRODUCTION

Staphylococcus is non-spore-forming cocci, a genus of Gram positive belongs to the *Micrococcaceae* family. These bacteria are generally present as normal human microbiota of the skin and nasal cavity. However, *Staphylococcus aureus*, *Staphylococcus hominis, Staphylococcus haemolyticus*, *Staphylococcus epidermidis,* and *Staphylococcus saprophyticus* are pathogenic in nature. *S. aureus* is proved to be the most pathogenic bacteria. It is able to coagulate plasma as it is coagulate positive in nature. It is commonly found in hospital and community-acquired nosocomial diseases. It is accountable as causative of a broad spectrum of skin diseases [1,2]. *S. aureus* has the ability to produce a wide range of toxins which include enterotoxins cause food poisoning, cytotoxins (general systemic toxins), and toxic shock superantigens [3] which leads to mild skin infection to serious life-threatening diseases [4]. In the 1880s, *S. aureus* was discovered causing skin and tissue infection and food poisoning. However, later, it becomes resistant to penicillin. Methicillin was used for the treatment of *S. aureus* infection. In 1961, *S. aureus* was given a name methicillin-resistant *S. aureus* (MRSA) as it becomes resistant to beta-lactams including amoxicillin and methicillin. The major issue with the species of *S. aureus* is its resistance toward antibiotics [5]. The recognition of the antimicrobial resistance pattern is required for a researcher to widely spread a pragmatic and pathogen-specific therapy. The various classes of antimicrobial agents have become less effective due to the emergence of antimicrobial resistance often due to the selective pressure of antimicrobial usage [6]. This selective pressure is the result of extensive use of antibiotics and the overuse of existing drugs [7].

METHODS

Collection of sample

For the isolation of *Staphylococcus,* skin samples were collected in a sterile container using a sterile swab and transferred aseptically to the laboratory at 40°C for further testing.

Isolation of *Staphylococcus*

The isolation of bacteria was done using selective media, i.e., Mannitol salt agar. After the inoculation of the swab sample on the plate, it was incubated for 24 h at 37°C. Presumptive *S. aureus* identified by the fermentation of mannitol as it produces yellow colonies. After the 24 h of incubation, the colonies obtained were further streaked to obtain the pure culture of bacteria [8].

Identification

The process of identification was done by morphological examination and biochemical tests. Gram staining was performed for the morphological identification. The various biochemical tests performed were citrate test, catalase test, oxidase test, Methyl Red - Voges Proskauer test, and sugar fermentation test [9-11].

Antibiotic susceptibility test

The commonly used antibiotics for the treatment of *S. aureus* associated diseases were tested for antibiotic susceptibility screening against these bacteria. The pure isolate was identified and selected for further study, by two methods: Spot-on-lawn and disk-diffusion method. Mueller–Hinton agar plates were prepared and 24 h old culture was inoculated. Antibiotic discs of different concentrations and various antibiotics were used and placed over the spread plates incubated at 37°C for 24 h. An evaluation was done on the basis of the size of the zone of inhibition (ZOI) [12].

RESULTS

Out of 56 isolated samples, 9 strains were studied after isolating a pure colony on selective media. One strain was selected on the basis of biochemical characterization. Pure isolated bacteria showed yellow-colored colonies on Mannitol salt agar media (Fig. 1) which confirmed it as *S. aureus* and found to be Gram positive as showed purple-colored grapes like the cluster in round shape (Fig. 2) (Table 1). The biochemical tests were catalase positive, i.e., culture showed bubble formation after adding the hydrogen peroxide (Fig. 3), citrate positive (after 24 h

incubation of inoculated Simmons' citrate agar color has changed from green to blue) (Fig. 4), oxidase positive, and methyl red positive tests (Table 2).

The antibiotic susceptibility of a selective isolate of *S. aureus* isolates revealed varying degrees of susceptibility patterns. Minimum inhibitory concentration has been calculated on the basis of ZOI for a different antibiotic with various ranges of concentrations. It has been found that the strain has shown maximum sensitivity toward tetracycline and chloramphenicol (Figs. 5-7). It was resistant toward nalidixic acid and ampicillin. The strain was also sensitive against ceftazidime, kanamycin, cefotaxime, and ciprofloxacin. A table has been formulated for different results which depict its sensitivity pattern (Tables 3-6).

The concentration used for all line therapy antibiotics and other antibiotics ranged from 0.01 mcg/disc to 240 mcg/disc. The minimum effective concentration of ceftazidime was 4 mcg and ZOI formed was 4 mm. Ampicillin and cefotaxime showed its affectivity at minimum concentration 32 mcg and ZOI formed was 5 mm and 7 mm, respectively.

DISCUSSION

Omoigberale *et al*. investigated the antibiotic resistance pattern of *S.aureus*, isolated from vaginal and urethral swab specimens. The authors found that isolates were more sensitive for chloramphenical and tetracycline and resistant for nalidixic acid and ampicillin. These results are found to be similar to our study indicated [13]. In our study, it has been concluded that *S. aureus* is found to be more resistant toward ampicillin and nalidixic acid and susceptible for chloramphenicol, cefotaxime, and tetracycline which is in contrast with the study of Salau *et al.* according to which antibiotic susceptibility pattern of *S. aureus* shows resistance to ampicillin (90.2%), chloramphenicol (13.1%), cefoxitin (32.8%), and tetracycline (13.1%) [14]. MRSA is found to be highly resistant to gentamicin (76%), erythromycin (67.03%), and ciprofloxacin (65.09%) [15].

A recent study on resistance pattern of *S. aureus* performed was showed that *S. aureus* isolates were more sensitive to linezolid (96.8%) than

MIC: Minimum inhibitory concentration

tetracycline (90.9%) and piperacillin/tazobactam (80.6%). These results are also similar to our study [16].

In the previous study, ampicillin recorded the highest rate of resistance of 90.2% with a sensitivity of 9.8%. The ability of *S. aureus* to resist this antibiotic is due to the ability of *S. aureus* to produce a plasmid-encoded beta-lactamase that hydrolyzes the beta-lactam ring of this class of antibiotic which is essential for its antimicrobial activities [17], and also, the high resistance to ampicillin could be due to the misuses or abuse of antibiotics which is common phenomenon in developing countries [18,19].

The intermediate resistance for cefotaxime has been founded by a previous study. This agrees with the result of the present study which shows resistance of *S. aureus* toward cefotaxime at concentration 16 mcg produced ZOI 32 mm [20].

S. aureus has been found to be more sensitive for chloramphenicol and it has been reported for the use of chloramphenicol antibiotic in case of multidrug-resistant Gram-positive bacteria [21]. This interpretation is exact as our study has proved the effectiveness of chloramphenicol even at minimum concentration [22,23].

Statistical analysis

For the statistical analysis, one-way ANOVA used to determine the significance of the results obtained. Level of significance was adjusted at 0.05 and results were said to be significant if their

$p<0.05$ and F_{crit}<F-value according to one-way ANOVA. Minimum inhibitory concentrations of all the antibiotics calculated show that chloramphenicol, kanamycin, and trimethoprim are more effective in first-line antibiotics (Fig. 8), second-line antibiotics, and third-line antibiotics, respectively (Graphs 1-3).

Fig. 8: Effect of trimethoprim

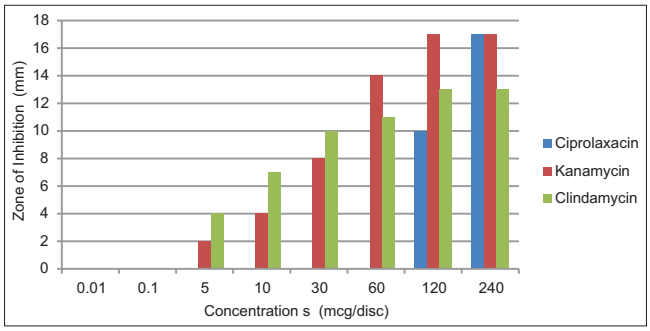
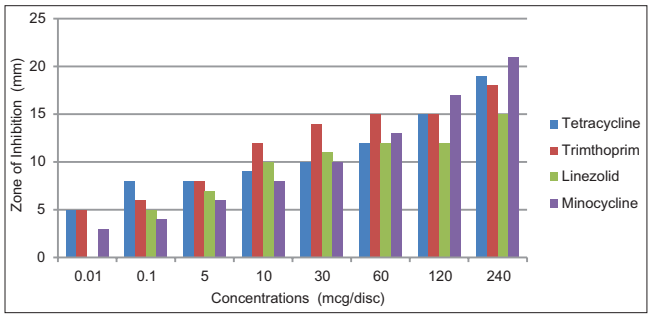


Graph 2: Zone of inhibition of second-line antibiotics as various concentrations



Graph 3: Zone of inhibition of third-line antibiotics as various concentrations

CONCLUSION

In the present investigation, it was found that *S. aureus* shows sensitivity toward first-, second-, third-line and other antibiotic. The bacteria found to be more sensitive toward third-line antibiotics, and minimum inhibitory concentration of antibiotics found to be is 0.01 mcg/disc.

ACKNOWLEDGMENT

The author wants to show gratitude to Mr. Nitin Sharma of orbit biotech for his ideas and suggestions at each step of my work. Moreover, author wants to special thank IK Gujral Punjab Technical University, Jalandhar, for providing me opportunity of doing the research work.

AUTHORS' CONTRIBUTIONS

Mittu B and Neha conceived and designed the experiments. Neha collected samples and performed laboratory analysis. Begum Z and Kaur H guide to wrote the manuscript and finalize the data. All authors have read and approved the final draft of the manuscript.

CONFLICTS OF INTEREST STATEMENT

The author(s) declared no potential conflicts of interest with respect to research, authorship, and/or publication of this article.
